Introduction

Primary canaliculitis is chronic inflammation of the proximal lacrimal pathway. The most common signs and symptoms are epiphora, medial canthal swelling, punctal or canalicular edema, pouting punctum, lower eyelid erythema, concretions, and mucopurulent discharge. As the manifestations of canaliculitis are similar to other diseases of the lacrimal apparatus, in many cases the diagnosis is delayed or misdiagnosed as chronic conjunctivitis, chalazion, or dacryocystitis, resulting in inadequate or incorrect treatment.

Materials and Methods

The medical records of patients diagnosed as having primary canaliculitis in the oculoplasty unit of our hospital between May 2014 and May 2021 were reviewed retrospectively. Ethics committee approval was obtained from the Ankara Bilkent City Hospital Clinical Research Ethics Committee (date of approval: 17/11/2021; protocol no: E1/2114/2021). The diagnosis of primary canaliculitis was based on clinical symptoms and signs.
Data including patients’ demographic characteristics, symptoms, symptom durations, previous clinical diagnoses, treatments, and long-term outcomes were collected. All patients were diagnosed based on clinical findings such as epiphora, punctal or canalicular edema, erythema (Figure 1), concretions (Figure 2), and purulent discharge from the punctum upon gentle pressure. Figure 2 shows one of our patients with sulfur granules.

Inclusion criteria were the presence of clinical findings suggesting typical canaliculitis and patent lacrimal syringing of the unaffected canaliculi. Exclusion criteria were cases of secondary canaliculitis due to foreign body in the punctum and canaliculus (e.g., eyelash, punctal plug) and obstruction of nasolacrimal duct drainage.

We applied two different treatment modalities. Intracanalicular antibiotic therapy was administered to patients who presented early (within 6 months) and had mild symptoms, patent lacrimal syringing through the unaffected canaliculi, dacryoliths, and purulent discharge from the punctum when mild pressure was applied. For patients who presented late (after 6 months; dacryoliths tend to be indurated in the late period), had recurrent canaliculitis, and/or were misdiagnosed underwent canaliculotomy and curettage of canalicular content with dacryolith removal. Depending on clinical severity, some patients received postoperative intracanalicular antibiotic treatment daily for the first week, then weekly for one month (Figure 3).

In intracanalicular antibiotic therapy without surgery, the canaliculus was irrigated with cefuroxime (750 mg/mL, 6 mL; Deva Holding, İstanbul, Türkiye) once a day for 5 days. A wide spectrum of topical antibiotics was given 8 times a day until the assessment of microbiologic culture results.

In surgical treatment, after local anesthesia, a Bowman lacrimal probe was passed into the affected canaliculus and an incision was made with a number 11 blade in the affected canaliculus. Canalicular curettage was performed using a chalazion curette. The canaliculi were irrigated with cefuroxime (750 mg/mL, 6 mL). The patients were treated with hot compresses and topical fluoroquinolone 8 times daily for 10 days. After canaliculotomy, intracanalicular cefuroxime was applied daily for the first week, then weekly for one month.

The antibiotic regimen was refined according to culture results and sensitivities. No silicone intubation or reconstruction was performed.

Dacryoliths and purulent material obtained during surgery were sent to the microbiology laboratory for analysis using anaerobic transport medium. For patients who received only intracanalicular antibiotic therapy, mucopurulent material expressed from the affected canaliculus before antibiotic irrigation was sent to the microbiology laboratory. Direct Gram staining revealed gram-positive, branching filamentous structures. Cultures were performed to ascertain the presence of aerobic and anaerobic bacteria and fungi. Columbia agar was incubated at 37 °C in anaerobic conditions for 5 days. Blood agar and MacConkey agar plates were incubated at 37 °C for 24-48 hours. Sabouraud dextrose agar plates were incubated at both 25 °C and 37 °C.

Results

Of 26 patients who consented to treatment, 17 (65.4%) were female and 9 (34.6%) were male. The mean age was 50.6±16.4 years (range: 9-80 years). Canaliculitis affected the right eye in 11 patients, the left eye in 13 patients, and was bilateral in 2 patients. Inferior canalicular involvement was more frequent (73%). The most common complaint was epiphora (46.1%). Sixteen patients (61.5%) were misdiagnosed as having chronic conjunctivitis and treated previously. Two patients presented for unresolved epiphora after dacryocystorhinostomy. Other causes of hospital admission were purulent discharge, itching, redness, pain, and swelling of the canalicular area. The mean time from symptom onset to canaliculitis diagnosis was 18.2±14.3 months (range: 1-60 months). The demographic characteristics, treatment, and follow-up data of the patients are shown in Table 1.

Canaliculotomy and curettage of canalicular content with dacryolith removal were performed in 23 patients. After surgery, antibiotic irrigation of the canaliculus was added to the treatment

![Figure 1](image1.png) Clinical appearance of the right inferior punctum before treatment in a patient with primary canaliculitis. Hyperemia of the conjunctiva and edematous inferior canaliculus are evident.

![Figure 2](image2.png) Typical sulfur granule appearance in canaliculitis
regimen in 12 of these 23 patients. The remaining 3 patients who did not undergo surgery received intracanalicular antibiotic therapy. All of these patients had been administered topical treatment with fluoroquinolone.

The most cultured organism was *Actinomyces* (6 patients). *Gemella* (1 patient), *Porphyromonas* (1 patient), *Candida parapsilosis* (1 patient), and *Citrobacter koseri* (1 patient) were also established in culture (Table 2). The mean follow-up time was 26.2±23.7 months (range: 6-83 months). Signs and symptoms resolved in all patients within 1 month. In 2 patients, recurrence occurred at 4 and 16 months after treatment. Canaliculotomy and curettage of canalicular content with dacryolith removal was performed in one of these patients, and intracanalicular antibiotic irrigation was done for the other. After appropriate treatment, no further recurrence was seen in either patient over 24-month follow-up. In 1 patient, iatrogenic canaliculus blockage was diagnosed during follow-up.

**Discussion**

The canaliculi are an important component of the lacrimal drainage system. They begin at the lacrimal puncta and mostly converge to form the common canaliculus. Canaliculitis is inflammation of the lacrimal canaliculus and accounts for only 2% to 4% of all patients with lacrimal pathology. The condition may be misdiagnosed and treated as conjunctivitis, blepharitis, dacryocystitis, or chalazion, thus leading to prolonged morbidity. The current study aimed to assess patients with primary canaliculitis and increase awareness of this rare and diagnostically challenging condition.

Canaliculitis is classified as either primary or secondary. While primary canaliculitis is usually caused by an infection, secondary canaliculitis is most commonly associated with punctal plug insertion for the treatment of dry eye, intracanalicular plug migration, or a foreign body in the punctum or canaliculus.

We only included patients with primary canaliculitis in this study.
Older women have a higher prevalence of canaliculitis in the literature. In our study, females (65.4%) were more affected than males (34.6%) and the patients' mean age was 50.6±16.4 years (range: 9-80 years). Our findings are consistent with the literature.

The masking clinical manifestations of canaliculitis and low awareness among general ophthalmologists often lead to late diagnosis. Sixteen of our 26 patients were previously misdiagnosed and treated for chronic conjunctivitis. The mean duration of symptoms prior to canaliculitis diagnosis in our study was 18.2±14.3 months (range: 1-60 months). This is longer than the intervals reported in two other studies by Kaliki et al. and Kim et al. For this reason, we think that increased awareness is needed to enable early diagnosis, and this condition should be considered when patients present with complaints of epiphora or recurrent conjunctivitis.

Dacryocystography and ultrasound biomicroscopy are widely used for the diagnosis of canaliculitis. However, the use of a detailed diagnostic tool such as dacryocystography can lead to scar tissue because of iatrogenic trauma and is not absolutely necessary for diagnosis. In the present study, all patients were diagnosed based on clinical manifestations (epiphora, punctal or canicular edema, erythema, concretions, and purulent discharge expressed from the punctum with gentle pressure). We did not use dacryocystography or ultrasound biomicroscopy.

Canaliculitis can be misdiagnosed as dacyrocystitis or nasolacrimal duct obstruction. Patent irrigation of the nasolacrimal duct through the unaffected canaliculus of the same eye is important in the differential diagnosis.

The prevalence of inferior canaliculus involvement was higher (73%) in the present study compared to other studies. To our knowledge, there is no explanation in the literature regarding which canaliculi are most affected and the reason for this. Our findings may be related to gravity and the anatomical structure of the inferior canaliculus. The lower canaliculi are almost entirely horizontal and taller than the upper canaliculi, and gravity may predispose the lower canaliculi to bacterial accumulation. In contrast to our study, Kim et al. reported that the upper and lower canaliculi were equally affected, while Vécei et al. reported that the upper canaliculi was more frequently involved. Most of the patients in our study had unilateral involvement (92%).

Treatment with only topical antibiotic drops, antibiotic irrigation of the canaliculi, or punctal curettage alone is associated with high recurrence rates. This is because antibiotics are unable to penetrate canicular concretions. Kaliki et al. argued that 41% of patients who were managed without surgery required additional treatment. No additional treatment was needed by our patients treated with intracanalicular antibiotic irrigation. Their symptoms completely resolved. However, these patients needed to come to the hospital more often than patients treated with surgery. Concretions may prevent antibiotics from killing the bacteria and are therefore one of the main risk factors for recurrent canaliculitis.

Curettage with or without one-snip punctoplasty and canaliculotomy are the recommended approaches to the surgical treatment of primary canaliculitis. Canaliculotomy can occur in association with canaliculitis and may lead to canaliculitis and bacterial propagation. Canaliculotomy was seen in one patient in our study. Yuksel et al. demonstrated that in cases without serious dilation, punctotomy/canalicular intubation and curettage may be sufficient for treatment. Canaliculotomy provides a higher success rate, but scarring and dysfunction of the lacrimal pump may occur. Canaliculoplasty may have an important role in the prevention of canaliculitis. Additionally, one-snip punctoplasty was found to be efficacious in cases without significant canaliculitis.

In the literature, there is one study that compared anatomical and functional success rates between patients with and without silicone tube intubation. Wang et al. reported that canaliculotomy with silicone tube intubation showed better outcomes, with significantly higher anatomical (100% vs. 73.8%) and functional success rates (87.5% vs. 60.9%) than in the group without silicone tube intubation. However, complete resolution of canaliculus edema, erythema, and purulent discharge was seen in all patients postoperatively, and no recurrent infections were observed in any of the patients during follow-up. Su et al. observed complete resolution in 78.6% of patients after canaliculotomy with stent placement. In contrast, in another study complete resolution was achieved in 97.2% of the patients after canaliculotomy and curettage without stent intubation. In the current study, no stent placement was performed and complete remission was achieved in 92% of the patients with a mean follow-up time of 26.2±23.7 months. Unfortunately, performing canaliculotomy with stent intubation was not an option because of the higher cost of stents in our hospital. Nevertheless, our results clearly demonstrate that canaliculotomy without stent intubation may be a good choice for these patients.

In our study, only one patient had canaliculus obstruction at follow-up, while the other patients had good canaliculus function. We achieved a high functional success rate using canaliculotomy and curettage of canicular content with dacrolyth removal.

Canaliculitis severity and symptom duration are important criteria guiding our treatment approach. We applied intracanalicular antibiotics to patients with early presentation (within 6 months) and mild symptoms (3 patients). However, antibiotic irrigation is not appropriate for patients with accumulated stones in the canaliculi and severe symptoms. In these patients, we performed canaliculotomy and curettage of canicular content with dacrolyth removal. This surgical procedure was performed for 23 of our 26 patients. After surgery, antibiotic irrigation of the involved canaliculus was added to the treatment regimen if the patients had severe symptoms, recurrent canaliculitis, and presence of concretions (Figure 3).
In the literature, success rates in the conservative treatment of primary canaliculitis vary between 0% and 34.7%, while 80-100% recovery is reported after canaliculotomy.13,16,18,19 In our study, complete resolution of primary canaliculitis was noted in 100% of our patients in long-term postoperative follow-up. Two patients had recurrence 4 and 16 months after treatment. Canaliculotomy and curettage of canalicular content with dacryolith removal was repeated in one of the patients, and intracanalicular antibiotic irrigation was performed for the other patient. No further recurrence was seen in either patient in 24 months of follow-up.

Conventionally, the causative pathogen of canaliculitis is reported to be Actinomyces israelii, an anaerobic gram-positive bacillus. It is associated with chronic purulent granulomatous infection with typical sulfur granules.80 Most recently, studies have shown an increased incidence of Staphylococcus and Streptococcus species.9,10,11,13 Many other uncommon organisms like Eikenella, Lactococcus, Nocardioides, and fungi also have been isolated from patients with canaliculitis.6 Concretions were initially considered pathognomonic of Actinomyces, but many other organisms have also been associated with concretions in other studies.10,13,15,21 In the present study, discharge and/or concretions from all patients were sent to the microbiology laboratory for evaluation and microbiological cultures were positive in only 10 patients (38%). Actinomyces israelii was most frequently isolated organism in the current study (23%), and other cultured organisms included Gemella, Porphyromonas, Candida parapsilosis, and Citrobacter koseri.

This study reflects the long-term results of a tertiary ophthalmology center to which patients were referred from many different centers in our country. However, the main limitation is its retrospective design. Another limitation is that we could not make a comparison between patients who received only intracanalicular antibiotic therapy and those who underwent surgery, because the number of patients who received early treatment was small. However, this led us to believe that diagnosis is usually delayed in these patients, so we need to raise our awareness of early diagnosis.

Conclusion
Canaliculitis is an uncommon lacrimal pathway disease that can be overlooked and misdiagnosed for long periods. As a result, the appropriate treatment is generally delayed. The most common symptom in our patients was epiphora. All patients with epiphora and chronic conjunctivitis should be examined carefully for canaliculitis. The recommended treatment is canaliculotomy and curettage of canalicular content with dacryolith removal. In spite of appropriate treatment, the possibility of recurrence should always be kept in mind.
